Abstract

A 3-manifold is Haken if it contains a topologically essential surface. The Virtual Haken Conjecture says that every irreducible 3-manifold with in nite fundamental group has a nite cover which is Haken. Here, we discuss two interrelated topics concerning this conjecture.

First, we describe computer experiments which give strong evidence that the Virtual Haken Conjecture is true for hyperbolic 3-manifolds. We took the complete Hodgson-Weeks census of 10,986 small-volume closed hyperbolic 3-manifolds, and for each of them found nite covers which are Haken. There are interesting and unexplained patterns in the data which may lead to a better understanding of this problem.

Second, we discuss a method for transferring the virtual Haken property under Dehn lling. In particular, we show that if a 3-manifold with torus boundary has a Seifert bered Dehn lling with hyperbolic base orbifold, then most of the Dehn lled manifolds are virtually Haken. We use this to show that every non-trivial Dehn surgery on the gure-8 knot is virtually Haken.

1 Introduction

Let \mathcal{M} be an orientable 3-manifold. A properly embedded orientable surface $S \not\in S^2$ in \mathcal{M} is *incompressible* if it is not boundary parallel, and the inclusion $_1(S)$! $_1(\mathcal{M})$ is injective. A manifold is *Haken* if it is irreducible and contains an incompressible surface. Haken manifolds are by far the best understood class of 3-manifolds. This is because splitting a Haken manifold along an incompressible surface results in a simpler Haken manifold. This allows induction arguments for these manifolds.

However, many irreducible 3-manifolds with in nite fundamental group are not Haken, e.g. all but 4 Dehn surgeries on the gure-8 knot. It has been very hard to prove anything about non-Haken manifolds, at least without assuming some sort of additional Haken-like structure, such as a foliation or lamination.

Sometimes, a non-Haken 3-manifold M has a nite cover which is Haken. Most of the known properties for Haken manifolds can then be pushed down to M (though showing this can be di cult). Thus, one of the most interesting conjectures about 3-manifolds is Waldhausen's conjecture [54]:

1.1 Virtual Haken Conjecture Suppose M is an irreducible 3-manifold with in nite fundamental group. Then M has a nite cover which is Haken.

A 3-manifold satisfying this conjecture is called *virtually Haken*. For more background and references on this conjecture see Kirby's problem list [38], problems 3.2, 3.50, and 3.51. See also [12, 13] and [40, 39] for some of the latest results toward this conjecture. The importance of this conjecture is enhanced because it's now known that 3-manifolds which are virtually Haken are geometrizable [27, 26, 49, 41, 42, 25, 9].

There are several stronger forms of this conjecture, including asking that the nite cover be not just Haken but a surface bundle over the circle. We will be interested in the following version. Let M be a closed irreducible 3-manifold. If $H_2(M;\mathbb{Z}) \not \in 0$ then M is Haken, as any non-zero class in $H_2(M;\mathbb{Z})$ can be represented by an incompressible surface. Now $H_2(M;\mathbb{Z})$ is isomorphic to $H^1(M;\mathbb{Z})$ by Poincare duality, and $H^1(M;\mathbb{Z})$ is a free abelian group. So if the rst betti-number of M is $_1(M) = \dim H_1(M;\mathbb{R}) = \dim H^1(M;\mathbb{R})$, then $_1(M) > 0$ implies M is Haken. As the cover of an irreducible 3-manifold is irreducible [41], a stronger form of the Virtual Haken Conjecture is:

1.2 Virtual Positive Betti Number Conjecture Suppose M is an irreducible 3-manifold with in nite fundamental group. Then M has a nite cover N where $_{1}(N) > 0$.

We will say that such an M has *virtual positive betti number*. Note that $_1(N) > 0$ if and only if $H_1(N;\mathbb{Z})$, the abelianization of $_1(N)$, is in nite. So an equivalent, more algebraic, formulation of Conjecture 1.2 is:

1.3 Conjecture Suppose M is an irreducible 3-manifold. Assume that $_1(M)$ is in nite. Then $_1(M)$ has a nite index subgroup with in nite abelianization.

Here, we focus on this form of the Virtual Haken Conjecture because its algebraic nature makes it easier to examine both theoretically and computationally. While in theory one can to use normal surface algorithms to decide if a manifold is Haken [37], in practice these algorithms are prohibitively slow in all but the simplest examples. Computing homology is much easier as it boils down to computing the rank of a matrix. Also, it's probably true that having virtual positive betti number isn't much stronger than being virtually Haken (see the discussion of [40] in Section 11 below).

1.4 Outline of the paper

This paper examines the Virtual Haken Conjecture in two interrelated parts:

Experiment: Sections 2-6

Here, we describe experiments which strongly support the Virtual Positive Betti Number Conjecture. We looked at the 10,986 small-volume hyperbolic manifolds in the Hodgson-Weeks census, and tried to show that they had virtual positive betti number. In all cases, we succeeded. It was natural to restrict to hyperbolic 3-manifolds for our experiment since, in practice, all 3-manifolds are geometrizable and the Virtual Positive Betti Number Conjecture is known for all other kinds of geometrizable 3-manifolds.

Section 2 gives an overview of the experiment and discusses the results and limitations of the survey. Sections 3 and 4 describe the techniques used to compute the homology of the covers. Section 5 discusses some interesting patterns that we found among the covers where the covering group is a simple group. Some further questions are given in Section 6.

Examples and Dehn lling: Sections 7 - 12

Here we consider Dehn llings of a xed 3-manifold M with torus boundary. Generalizing work of Boyer and Zhang [5], we give a method for transferring

virtual positive betti number from one lling of M to another. Roughly, Theorem 7.3 says that if M has a lling which is Seifert bered with hyperbolic base orbifold, then most Dehn llings have virtual positive betti number. We use this to give new examples of manifolds M where all but nitely many Dehn llings have virtual positive betti number. In Section 9, we show this holds for most surgeries on one component of the Whitehead link.

In the case of gure-8 knot, we use work of Holt and Plesken [35] to amplify our results, and prove that every non-trivial Dehn surgery on the gure-8 knot has virtual positive betti number (Theorem 10.1).

In Section 11, we discuss possible avenues to other results using llings which are Haken rather than Seifert bered. This approach is easiest in the case of toroidal Dehn llings, and using these techniques we prove (Theorem 12.1) that all Dehn llings on the sister of the gure-8 complement satisfy the Virtual Positive Betti Number Conjecture.

Acknowledgments

The rst author was partially supported by an NSF Postdoctoral Fellowship. The second author was partially supported by NSF grants DMS-9704135 and DMS-0072540. We would like to thank Ian Agol, Daniel Allcock, Matt Baker, Danny Calegari, Greg Kuperberg, Darren Long, Alex Lubotzky, Alan Reid, William Stein, and Dylan Thurston for useful conversations. We also thank of the authors of the computer programs SnapPea [56] and GAP [28] which were critical for our computations.

2 The experiment

2.1 The manifolds

We looked at the 10,986 hyperbolic 3-manifolds in the Hodgson-Weeks census of small-volume closed hyperbolic 3-manifolds [56]. The volumes of these manifolds range from that of the smallest known manifold (0.942707:::) to 6.5. While there are in nitely many closed hyperbolic 3-manifolds with volume less than 6.5, there are only nitely many if we also bound the injectivity radius from below. The census manifolds are an approximation to all closed hyperbolic 3-manifolds with volume < 6.5 and injectivity radius > 0.3.

A more precise description of these manifolds is this. Start with the Callahan-Hildebrand-Weeks census of cusped nite-volume hyperbolic 3-manifolds, which

is a complete list of the those having ideal triangulations with 7 or fewer tetrahedra [34, 8]. The closed census consists of all the Dehn llings on the 1-cusped manifolds in the cusped census, where the closed manifold has shortest geodesic of length >0.3.

Only 132 of the 10,986 manifolds have positive betti number. It is also worth mentioning that many (probably the vast majority) of these manifolds are non-Haken. For the 246 manifolds with volume less than 3, exactly 15 are Haken [19].

2.2 Computational framework

For each 3-manifold, we started with a nite presentation of its fundamental group G, and then looked for a nite index subgroup H of G which has in nite abelianization. There is a fair amount of literature on how nd such an H, because nding a nite index subgroup with in nite abelianization is one of the main computational techniques for proving that a given nitely presented group is in nite. See [43] for a survey. The key idea which simplifies the computations is contained in [35], which we used in the form described in Section 3.

We used SnapPea [56] to give presentations for the fundamental groups of each of the manifolds in the closed census. We then used GAP [28] to nd various nite index subgroups and compute the homology of the subgroups (see Sections 3-4).

2.3 Types of covers

When looking for a subgroup with positive betti number, we tried a number of di erent types of subgroups. Some types were much better at producing homology than others. Those that worked well were:

Abelian/p-group covers with exponent 2 or 3.

Low (< 20) index subgroups. Coset enumeration techniques allow one to enumerate low-index subgroups [52]. Given such a subgroup H < G, we looked at the largest normal subgroup contained in H, to maximize the chance of H nding homology.

Normal subgroups where the quotient is a $\,$ nite simple group. These were found by choosing the simple group in advance and then $\,$ nding all epimorphisms of $\,$ onto that group.

The following types were ine cient in producing homology:

Abelian/nilpotent covers with exponents > 3.

Dihedral covers.

Intersections of subgroups of the types listed in the rst list (the useful types).

It would be nice to have heuristics which explain why some things worked and others didn't (we plan to explore this further in [21]). Also, while intersecting subgroups was not e cient in general, there were certain manifolds where the only positive betti number cover we could nd were of this type.

2.4 Results

We were able to nd positive betti number covers for all of the Hodgson-Weeks census manifolds. For most of the manifolds, it was easy to nd such a cover. For instance, just looking at abelian covers and subgroups of index 6 works for 42% of the manifolds. See Table 1 for more about the degrees of the covers we used.

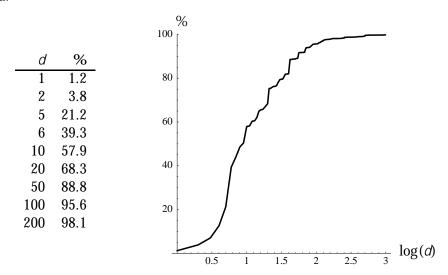

Table 1: The table at left shows the proportion of manifolds for which we found a cover with positive betti number of degree $\ensuremath{\mathcal{C}}$. Note this is just for the covers that we found, which are not always the positive betti number covers of smallest degree. The plot at right presents all of the data, where $\log(\ensuremath{\mathcal{C}})$ is base 10.

For each of the manifolds, we stored a presentation of the fundamental group and a homomorphism from that nitely presented group to S_n whose kernel has positive betti number. This information is available on the web at [20] together with the GAP code we used for the computations, and will hopefully be useful as a source of examples. The amount of computer time used to nd all the covers

was in excess of one CPU-year, but the amount of time needed to check all the covers for homology given the data available at [20] is only a few of hours.

There was one manifold in particular where it was very discult to and a cover with positive betti number. This manifold is N = s633(2;3). Its volume is 4.49769817315::: and $H_1(N) = \mathbb{Z}=79\mathbb{Z}$. The manifold N has a genus-2 Heegaard splitting, and is the 2-fold branched cover of the 3-bridge knot in Figure 1. One of the reasons that N was so discult is that I(N) has very

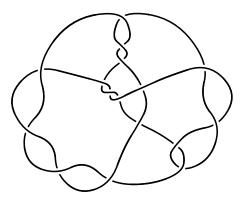

Figure 1: The 2-fold cover branched over this knot is the manifold N. Figure created with [36].

few low-index subgroups (the smallest index is 13). In the end, a search using Magma [4], turned up a subgroup of index 14 which has positive betti number. It is very hard to enumerate all nite-index subgroups for an index as large as 14, roughly because the size of S_n is n!; nding this index 14 subgroup took 2 days of computer time.

While $_1(N)$ has few subgroups of low index, it does have a reasonable number of simple quotients, and might be a good place to look for a co- nal sequence of covers which fail to have positive betti number. The manifold N is non-Haken, but it contains a essential lamination (and thus a genuine lamination [7]). Arithmetically, it is quite a complicated manifold | Snap [29] computes that the trace eld has a minimal polynomial p(x) whose degree is 51 and largest coe cient is about $4 10^7$. The coe cients of p are, starting with the constant term:

1, 24, 223, 929, 909, -6163, -20232, -2935, 79745, 121259, -57077, -428280, -507427, 689749, 2245466, -519994, -5455251, 355551, 9513149, -1958013,

2.5 Overlap with known results

The manifolds we examined have little overlap with those covered by the known results about the Virtual Haken Conjecture. The only general results are those of Cooper and Long [12, 13] building on work of Freedman and Freedman [24]. These are Dehn surgery results | they say that many \large" Dehn llings on a 1-cusped hyperbolic 3-manifold are virtually Haken. Because \large" Dehn llings usually have short geodesics, the Cooper-Long results probably apply to very few, if any, of the census manifolds.

2.6 Limitations

It's possible the behavior we found might not be true in general because the census manifolds are non-generic in a couple ways. First, they all have fundamental groups with presentations with at most 3 generators. About 75% have 2-generator presentations. For these manifolds, it seems that (at least most of the time) the number of generators and the Heegaard genus coincide. So most of these manifolds have Heegaard genus 2 or 3.

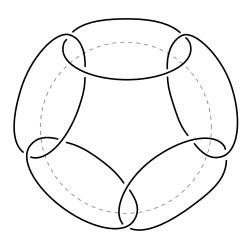

Figure 2: The minimally-twisted 5-chain link.

Moreover Callahan, Hodgson, and Weeks (unpublished) showed that almost all of the census manifolds are Dehn surgeries on a single 5-component link, the

minimally twisted 5-chain shown in Figure 2. Let L be this link and $M = S^3 \, n \, N(L)$ be its exterior. The link L is invariant under rotation of about the dotted grey axis. The induced involution of M acts on each torus in @M by the elliptic involution. Thus the involution of M extends to an orientation preserving involution of every Dehn lling of M. So almost all of the census manifolds have an orientation preserving involution where the xed point set is a link and underlying space of the quotient is S^3 . While any manifold which has a genus-2 Heegaard splitting has such an involution [3], this says that the other 25% of the census manifolds are also special. The presence of such an involution has proven useful in the past. For instance, it implies that the manifold is geometrizable. So it's possible that our computations only reflect the situation for manifolds of this type.

The 5-chain L is a truly beautiful link, and it's worth describing some of its properties here. The orbifold N which is M modulo this involution is easy to describe. Take the triangulation T of S^3 gotten by thinking of S^3 as the boundary of the 4-simplex. The 1-skeleton of T is called the *pentacle*, see Figure 3. If we take S^3 minus an open ball about each vertex in T, and label

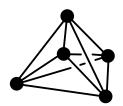

Figure 3: The pentacle.

what's left of each edge of the pentacle by $\mathbb{Z}=2\mathbb{Z}$, we get exactly the orbifold N!

We can put a hyperbolic structure on N and thus M by making each tetrahedron in T a regular ideal tetrahedron. Thus the volume of M is $10v_3 = 10.149416064$::, and further M is arithmetic and commensurable with the Bianchi group $PSL_2O(\frac{1}{-3})$. The symmetric group S_5 acts on the 4-simplex by permuting the vertices, inducing an action of S_5 on N. This action is exactly the group of isometries of N. The isometry group of M is $S_5 = \mathbb{Z} = 2\mathbb{Z}$, where the $\mathbb{Z} = 2\mathbb{Z}$ is the rotation about the axis.

The manifold M bers over the circle, and in fact every face of the Thurston norm ball is bered. Here's an explicit way to see that N bers over the interval I with mirrored endpoints (this bration lifts to a bration of M over S^1). Take

any Hamiltonian cycle in the 1-skeleton of T. The complementary edges also form a Hamiltonian cycle. Split the fat vertices of T (the cusps of N) in the obvious way in space so that these two cycles become the unlink, with cusps stretched between them. Then the special bers over the \mathbb{Z} -2 \mathbb{Z} endpoints of I are two pentagons, spanning the two Hamiltonian cycles. The other bers are 5-punctured spheres.

3 Techniques for computing homology

Given a nite index subgroup H of a nitely presented group G, a simpli ed version of the Reidemeister-Schreier method produces a matrix A with integers entries whose cokernel is the abelianization of H. Computing this matrix is not very time-consuming. The hard part of computing the rank of the abelianization of H is nding the rank of A. Computing the rank of a matrix is $O(n^3)$ if eld operations are constant time. We need to compute the rank over $\mathbb Q$ so the time needed is somewhat more than that (see Section 4). The side lengths of A are usually about n = [G:H], which at $O(n^3)$ is prohibitive for many of the covers that we looked at (the largest covering group we needed was $PSL_2\mathbb F_{101}$, whose order is 515,100).

So one wants to keep the degree of the cover, or really the size of the matrix involved, as small as possible. One way to do this, rst used in this context by Holt and Plesken [35], is the following application of the representation theory of nite groups. Suppose H is a nite index subgroup of G. Assume that H is normal, so the corresponding cover is regular. Set Q = G = H and let f: G! Q be the quotient map. The group Q acts on the homology of the cover $H_1(H;\mathbb{C})$, giving a representation of Q on the vector space $H_1(H;\mathbb{C})$. Another description of $H_1(H;\mathbb{C})$ is that it is the homology with twisted coe cients $H_1(G;\mathbb{C}Q)$. As a Q-module, $\mathbb{C}Q$ decomposes as $\mathbb{C}Q = V_1^{n_1} V_2^{n_2} V_k^{n_k}$ where the V_i are simple Q-modules and dim $V_i = n_i$. So

$$H_1(H) = H_1(G; \mathbb{C}Q) = H_1(G; V_1)^{n_1} \quad H_1(G; V_2)^{n_2} \quad H_1(G; V_k)^{n_k}$$

Since the dimensions of the V_i are usually much less than the order of O, the matrices involved in computing $H_1(G;V_i)$ are much smaller than the one you would get by applying Reidemeister-Schreier to the subgroup H. For instance, $PSL_2\mathbb{F}_p$ has order about $(1=2)p^3$, but every V_i has dimension about p. If we want to show that $H_1(H;\mathbb{C})$ is non-zero, we just have to compute that a single $H_1(G;V_i)$ is non-zero.

There are a couple of disculties in computing $H_1(G; V_i)$. First, to do the computation rigorously, we need to compute not over \mathbb{C} but over a site extension

of \mathbb{Q} . Now there is a eld k so that kQ splits over k the same way as $\mathbb{C}Q$ splits over \mathbb{C} . However, the matrices we need to compute $H_1(G;V_i)$ will have entries in k, whereas the matrix given to us by Reidemeister-Schreier has integer entries. If A is a matrix with entries in k, to compute its rank over \mathbb{Q} one can form an associated \mathbb{Q} -matrix B by embedding k as a subalgebra of $\mathrm{GL}_n\mathbb{Q}$ where n is $[k:\mathbb{Q}]$ (see e.g. [45]). The rank of B can then be computed using one the techniques for integer matrices. However, the size of B is the size of A times $[k:\mathbb{Q}]$, so this eats up part of the apparent advantage to computing just the $H_1(G;V_i)$.

The other problem is that we may not know what the irreducible representations of \mathcal{Q} are, especially if we don't know much about \mathcal{Q} . While computing the character table of a nite group is a well-studied problem, the problem of nding the actual representations is harder and not one of the things that GAP or other standard programs can do. Even when the representations of \mathcal{Q} are explicitly known (e.g. $\mathcal{Q} = PSL_2\mathbb{F}_p$), it can be time-consuming to tell the computer how to construct the representations. For more on computing the actual representations see [16, 44].

We used the following modi ed approach which avoids the two disculties just mentioned, while still reducing the size of the matrices considerably. Suppose we are given normal subgroup H and we want to determine if $H_1(H;\mathbb{C})$ is non-zero. Suppose U is a subgroup of Q. Note U is not assumed to be normal. The permutation representation of Q on $\mathbb{C}[Q=U]$ desums into irreducible representations, say $\mathbb{C}[Q=U] = V_1^{e_1} \quad V_2^{e_2} \quad V_k^{e_k}$. Let $K = f^{-1}(U)$, a nite index subgroup of G containing H. Then

$$H_1(K) = H_1(G; \mathbb{C}[Q=U]) = H_1(G; V_1)^{e_1} \quad H_1(G; V_2)^{e_2} \quad H_1(G; V_k)^{e_k}$$

Suppose that U is chosen so that every irreducible representation appears in $\mathbb{C}[Q=U]$, that is, every $e_i > 0$. Then we see that $H_1(H)$ is non-zero if and only if $H_1(K)$ is. As long as U is non-trivial, the index [G:K] = [Q:U] is smaller than [G:H] = #Q, so computing $H_1(K)$ is easier that computing $H_1(H)$. Returning to the example of $\mathrm{PSL}_2\mathbb{F}_p$, there is such a U of index about p^2 , whereas the order of $\mathrm{PSL}_2\mathbb{F}_p$ is about $p^3=2$. Looking at a matrix with side $O(p^2)$ is a big savings over one of side $O(p^3)$.

Moreover, nding such a U given Q is easy. First compute the character table of Q and the conjugacy classes of subgroups of Q (these are both well-studied problems). For each subgroup U of Q compute the character U of the permutation representation of Q on $\mathbb{C}[Q=U]$. Expressing U as a linear combination of the irreducible characters tells us exactly what the e_i are. Running through the U, we can U nd the subgroup of lowest index where all of the U of U of the U of the U of U

When we were searching for positive betti number covers, we used this method of replacing H with $K = f^{-1}(U)$ and computed the ranks of the resulting matrices over a nite eld \mathbb{F}_p . Once we had found an H with positive \mathbb{F}_p -betti number, we did the following to check rigorously that H has in nite abelianization. First, we went through aH the subgroups U of Q, till we found the U of smallest index such that $f^{-1}(U)$ has positive \mathbb{F}_p -betti number. For this U, we computed the \mathbb{Q} -betti number of $f^{-1}(U)$ using one of the methods described in Section 4. Doing this kept the matrices that we needed to compute the \mathbb{Q} -rank of small, and was the key to checking that the covers really had positive \mathbb{Q} -betti number. For instance, for the $\mathrm{PSL}_2\mathbb{F}_{101}$ -cover of degree 515,100 there was a U so that the intermediate cover $f^{-1}(U)$ with positive betti number had degree $\mathrm{Noly}^{\mathrm{u}}$ 5,050.

It's worth mentioning that the rank over \mathbb{Q} was very rarely di-erent than that over a small nite eld. Initially, for each manifold we found a cover where the \mathbb{F}_{31991} -betti number was positive. All but 3 of those 10,986 covers had positive \mathbb{Q} -betti number.

4 Computing the rank over Q

Here, we describe how we computed the \mathbb{Q} -rank of the matrices produced in the last section. Normally, one thinks of linear algebra as \easy", but standard row-reduction is polynomial time only if eld operations are constant time. To compute the rank of an integer matrix A rigorously one has to work over \mathbb{Q} . Here, doing row reduction causes the size of the fractions involved to explode. There are a number of ways to try to avoid this.

The rst is to use a clever pivoting strategy to minimize the size of the fractions involved [33, 32, 31]. This is the method built into GAP, and was what we used for the covers of degree less than 500, which su ced for 99:2% of the manifolds.

For all but about 7 of the remaining 94 manifolds, we used a simplified version of the p-adic algorithm of Dixon given in [17]. Over a large in itemed eld \mathbb{F}_p , we computed a basis of the kernel of the matrix. Then we used \rational reconstruction", a partial inverse to the map \mathbb{Q} ! \mathbb{F}_p to try to lift each of the \mathbb{F}_p -vectors to \mathbb{Q} -vectors (see [17, pg. 139]). If we succeeded, we then checked that the lifted vectors were actually in the kernel over \mathbb{Q} .

For 7 of the largest covers (degree 1,000{5,000), this simpli cation of Dixon's algorithm fails, and we used the program MAGMA [4], which has a very sophisticated p-adic algorithm, to check the ranks of the matrices involved.

5 Simple covers

To gain more insight into this problem, we looked at a range of simple covers for a randomly selected 1,000 of the census manifolds which have 2-generator fundamental groups. For these 1,000 manifolds we found all the covers where the covering group was a non-abelian nite simple group of order less than 33,000. For each cover we computed the homology. We will describe some interesting patterns we found.

First, look at Table 2. There, the simple groups are listed by their ATLAS [11] name (so, for instance, $L_{\Pi}(q) = \mathrm{PSL}_{\Pi}\mathbb{F}_q$), together with basic information about how many covers there are, and how many have positive betti number. There is quite a bit of variation among the di erent groups. For instance, only 11:3% of the manifold groups have $L_2(16)$ quotients but 42:8% have $L_3(4)$ quotients. Moreover, there are big di erences in how successful the di erent kinds of covers are at producing homology. Only half of the $L_2(37)$ covers have positive betti number, but almost all (97:5%) of the $U_4(2)$ covers do. There are no obvious reasons for these patterns (for instance, the success rates don't correlate strongly with the order of the group). It would be very interesting to have heuristics which explain them, and we will explore these issues in [21].

In terms of showing manifolds are virtually Haken, even the least useful group has a **Hit** rate greater than 10%. That is, for any given group at least 10% of the manifolds have a positive betti number cover with that group. So unless things are strongly correlated between di erent groups, one would expect that every manifold would have a positive betti number simple cover, and that one would generally nd such a cover quickly. Let Q(n) denote the n^{th} simple group as listed in Table 2. Set V(n) to be the proportion of the manifolds which have a positive betti number Q(k)-cover where k n. We expect that the increasing function V(n) should rapidly approach 1 as n increases. This is born out in Figure 4.

Figure 4 shows that the groups behave pretty independently of each other, although not completely as we will see. Let H(n) denote the hit rate for Q(n), that is the proportion of the manifolds with a Q(n) cover with positive betti number. If everything were independent, then one would expect

$$V(n)$$
 $V(n-1) + (1 - V(n-1))H(n)$:

If we let E(n) be the right-hand side above, and compare E(n) with V(n) we nd that E(n) - V(n) is almost always positive. To judge the size of this

Quotient	Order	Hit	HavCov	SucRat1	SucRat2
A_5	60	14.0	26.9	52.0	52.9

Table 2: **Hit** is the percentage of manifolds having a cover with this group which has positive betti number. **HavCov** is the percentage of manifolds having a cover with this group. **SucRate1** is the percentage of manifolds having a cover with this group which have such a cover with positive betti number. **SucRate2** is the percentage of covers with this group having positive betti number.

deviation, we look at

$$\frac{E(n) - V(n)}{1 - V(n-1)}$$
 which lies in [-0.007;0:13],

and which averages 0.022. In other words, V(n) - V(n-1) is usually about 2% smaller as a proportion of the possible increase than E(n) - V(n-1).

Geometry & Topology, Volume 7 (2003)

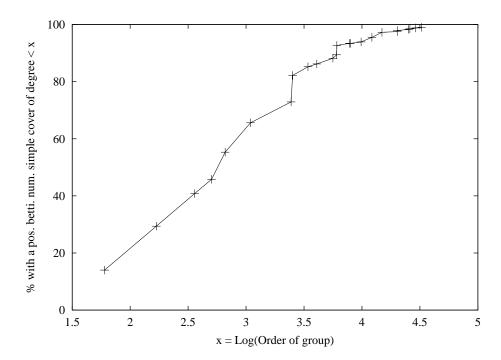

Figure 4: This graph shows how quickly simple group covers generate homology. Each + plotted is the pair $(\log(\#Q(n)); V(n))$, where the log is base 10. Thus the leftmost + corresponds to the fact that 14% of the manifolds have an A_5 cover with positive betti number. The second leftmost + corresponds to the fact that 29% of the manifolds have either an A_5 or an $L_2(7)$ cover with positive betti number, and so on.

For a graphical comparison, de ne $V^{\ell}(n)$ by the recursion

$$V^{\ell}(n) = V^{\ell}(n-1) + (1 - V^{\ell}(n-1))H(n)$$

and compare with V(n) in Figure 5.

Asymptotically, every non-abelian $\$ nite simple group is of the form $\ L_2(q)$, and so it's interesting to look at a modi ed $\ V(n)$ where we look only at the $\ Q(n)$ of this form. This is also shown in Figure 5.

5.1 Amount of homology

Suppose we look at a simple cover of degree d, what is the expected rank of the homology of the cover? The data suggests that the expected rank is linearly proportional to d. For the simple group Q(n), set R(n) to be the mean of $_1(N)$, where N runs over all the Q(n) covers of our manifolds (including

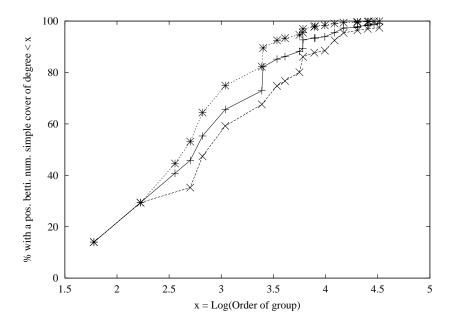

Figure 5: The top line plots $(\log(\#Q(n)); V^{\ell}(n))$, the middle line $(\log(\#Q(n)); V(n))$ (as in Figure 4), and the lowest line plots only the groups of the form $L_2(q)$.

those where $_1(N) = 0$). Figure 6 gives a plot of $\log R(n)$ versus $\log(\# Q(n))$. Also shown is the line y = x - 1.3 (which is almost the least squares t line y = 1.018x - 1.303). The data points follow that line, suggesting that:

$$\log R(n) = \log(\# Q(n)) - 1.3$$
 and hence $R(n) = \frac{\# Q(n)}{20}$. (1)

Now each of the 3-manifold groups we are looking at here are quotients of the free group on two generators F_2 . Let G be fundamental group of one of our 3-manifolds, say $G = F_2 = N$. Given a homomorphism G! Q(n), we can look at the composite homomorphism F_2 ! Q(n). Let H be the kernel of G! Q(n) and K the kernel of F_2 ! Q(n). Then the rank of $H_1(K)$ is #Q(n) + 1. As $H_1(H)$ is a quotient of $H_1(K)$, Equation 1 is says that on average, 5% of $H_1(K)$ survives to $H_1(H)$.

This amount of homology is not a priori forced by the high hit rate for the $\mathcal{Q}(n)$. For instance, $L_2(p)$ has order $(p^3-p)=2$ but has a rational representation of dimension p. Thus it would be possible for $L_2(p)$ covers to have

$$\log(R(n))$$
 (1=3) $\log(\#G(n)) + C$;

even if a large percentage of these covers had positive betti number. This data suggests that on a statistical level these 3-manifold groups are trying to behave

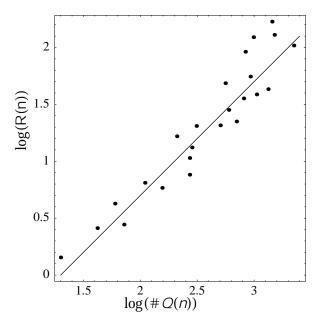

Figure 6: This plot shows the relationship between the expected rank and the degree of the cover. The line shown is y = x - 1.3.

like the fundamental group of a 2-dimensional orbifold of Euler characteristic -1=20.

Caveats

The data in Figure 6 is not based on the full Q(n) covers but on subcovers coming from a xed subgroup U(n) < Q(n), chosen as described in Section 3. The degree plotted is the degree of the cover that was used, that is [Q(n):U(n)] not the order of Q(n) itself, so the above analysis is still valid. Also, throughout Section 5 having positive betti number really means having positive betti number over \mathbb{F}_{31991} . Also, we originally used a list of the Hodgson-Weeks census which had a few duplicates and so there are actually 12 manifold which appear twice in our list of 1000 random manifolds.

5.2 Homology of particular representations

As discussed in Section 3, if we look at a cover with covering group Q, the homology of the cover decomposes into

$$H_1(G; V_1)^{n_1} \quad H_1(G; V_2)^{n_2} \qquad H_1(G; V_k)^{n_k};$$

Geometry & Topology, Volume 7 (2003)

Partition	Dim. of rep	Success rate	Mean homology
7	1	2%	0.0
1;6	6	22%	1.5
2;5	14	63%	19.8
1;1;5	15	64%	21.8
3:4	14	41%	11.0
1;2;4	35	70%	101.6
1;1;1;4	20	61%	20.7
1;3;3	21	61%	33.9

Table 3: The \mathbb{Q} -irreducible representations of A_7 . Success Rate is the percentage of covers where that representation appeared. Mean Homology is the average amount of homology that that representation contributed (the mean homology of an A_7 cover was 210.3).

where G is the fundamental group of the base manifold and the V_i are the irreducible Q-modules. For Q an alternating group, we looked at this decomposition and found that the ranks of the $H_1(G;V_i)$ were very strongly positively correlated. This contrasts with the relative independence of the ranks of covers with di erent Q(n).

We will describe what happens for A_7 , the other alternating groups being similar. The rational representations of A_7 are easy to describe: they are the restrictions of the irreducible representations of S_7 . They correspond to certain partitions of 7. Table 3 lists the representations and their basic properties. Table 4 shows the correlations between the ranks of the $H_1(G; V_i)$. Many of the correlations are larger than 0.5 and all are bigger than 0 (+1 is perfect correlation, -1 perfect anti-correlation and 0 the expected correlation for independent random variables). Figure 7 shows the distribution of the homology of the covers.

5.3 Correlations between groups

In the beginning of Section 5 we saw that the two events

having a Q(n)-cover with 1 > 0; having a Q(m)-cover with 1 > 0

were more or less independent of each other, though overall there was a slight positive correlation which dampened the growth of V(n). In the appendix, there is a table giving these correlations, was well one giving those between the events:

having a Q(n)-cover; having a Q(m)-cover:

	7	16	25	115	34	124	1114	133
7	1.00	0.01	0.11	0.08	0.15	0.17	0.02	0.13
16	0.01	1.00	0.22	0.09	0.23	0.19	0.18	0.19
25	0.11	0.22	1.00	0.63	0.65	0.79	0.37	0.61
115	0.08	0.09	0.63	1.00	0.52	0.80	0.75	0.78
34	0.15	0.23	0.65	0.52	1.00	0.73	0.50	0.65
124	0.17	0.19	0.79	0.80	0.73	1.00	0.65	0.89
1114	0.02	0.18	0.37	0.75	0.50	0.65	1.00	0.66
133	0.13	0.19	0.61	0.78	0.65	0.89	0.66	1.00

Table 4: Table showing the correlations between the ranks of $H_1(G; V_i)$ where the V_i are indexed by the partition of the corresponding representation.

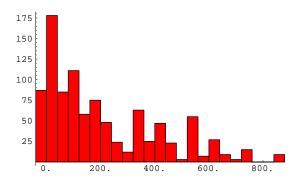

Figure 7: Plot showing the distribution of the ranks of the homology of the 964 covers with group A_7 . The x-axis is the amount of homology and the y-axis the number of covers with homology in that range.

Some of these correlations are much larger than one would expect by chance alone \mid for instance the correlation between

having a $L_2(7)$ -cover with $_1 > 0$; having a $L_2(8)$ -cover with $_1 > 0$

is 0.38. Moreover, there are very few negative correlations and those that exist are quite small. Overall, the average correlation is positive as we would expect from Section 5.

One way of trying to understand these correlations is to observe that almost all of these manifolds are Dehn surgeries on the minimally twisted 5-chain. Let us focus on the simpler question of correlations between having a cover with group Q(n) and having a cover with group Q(m). Let M be the complement of the 5-chain. Consider all the homomorphisms f_k : ${}_1M$! Q(n). Supposes

X is a Dehn lling on M along the ve slopes $\begin{pmatrix} 1 & 2 & 3 & 4 & 5 \end{pmatrix}$ where f is in $f(@_iM)$. The manifold X has a cover with group Q(n) if and only if there is an f_k where each f lies in the kernel of f_k restricted to $f_k = 1$ ($f_k = 1$). Thus having a cover with group $f_k = 1$ ($f_k = 1$) is determined by certain subgroups of the groups $f_k = 1$ ($f_k = 1$). If we consider a different group $f_k = 1$ ($f_k = 1$) we get a different family of subgroups of the $f_k = 1$ ($f_k = 1$). If there is a lot of overlap between these two sets of subgroups, there will be a positive correlation between having a cover with group $f_k = 1$ and having a cover with group $f_k = 1$ ($f_k = 1$) and having a cover with group $f_k = 1$ ($f_k = 1$). If there is little overlap then there will be a negative correlation. However, even looked at this way there seems to be no reason that the average correlation should be positive.

If we look at the same question for manifolds which are Dehn surgeries on the gure-8 knot (a simpli ed version of this setup) there are many negative correlations and the overall average correlation is 0. If we look at the question for small surgeries on the Whitehead link, the overall average correlation is positive and of similar magnitude of that for the 5-chain. If we also look at larger surgeries on the Whitehead link the average correlation drops somewhat. By changing the link we get a di erent pattern of correlations, and so it is unwise to attach much signi cance to these numbers.

6 Further questions

Here are some interesting further questions related to our experiment.

- (1) What happens for 3-manifolds bigger than the ones we looked at? Do the patterns we found persist? It is computationally di cult to deal with groups with large numbers of generators, which would limit the maximum size of the manifolds considered. But another di culty is how to nd a \representative" collection of such manifolds. (Some notions of a \random 3-manifold", which help with this latter question, will be discussed in [21]).
- (2) How else could the virtually Haken covers we found be used to give insight into these conjectures? For instance, one could try to look at the virtual bration conjecture. While there is no good algorithm for showing that a closed manifold is bered, one could look at the following algebraic stand-in for this question. If a 3-manifold bers over the circle, then one of the coe cients of the Alexander polynomial which is on a vertex of the Newton polytope is 1 (see e.g. [18]). One could compute the Alexander polynomial of the covers with virtual positive betti number and see how

- often this occurred. As many of our covers are quite small, computing the Alexander polynomial should be feasible in many cases.
- (3) One could use our methods to look at the Virtual Positive Betti Number conjecture for lattices in the other rank-1 groups that don't have Property T. This would be particularly interesting for the examples of complex hyperbolic manifolds where every congruence cover has $_1=0$. These complex hyperbolic manifolds were discovered by Rogawski [47, Thm. 15.3.1] and are arithmetic.

7 Transferring virtual Haken via Dehn lling

In the rest of this paper, we consider the following setup. Let M be a compact 3-manifold with boundary a torus. The process of Dehn Iling creates closed 3-manifolds from M by taking a solid torus D^2 S^1 and gluing its boundary to the boundary of M. The resulting manifolds are parameterized by the isotopy class of essential simple closed curve in @M which bounds a disc in the attached solid torus. If denotes such a class, called a slope, the corresponding Dehn lling is denoted by $M(\)$. Though no orientation of is needed for Dehn lling, we will often think of the possible as being the primitive elements in $H_1(@M;\mathbb{Z})$ and so $H_1(@M;\mathbb{Z})$ parameterizes the possible Dehn llings.

If you have a general conjecture which you can't prove for all 3-manifolds, a standard thing to do is to try to prove it for most Dehn llings on an arbitrary 3-manifold with torus boundary. For instance, in the case of the Geometrization Conjecture there is the following theorem:

7.1 Hyperbolic Dehn Surgery Theorem [53] Let M be a compact 3-manifold with @M a torus. Suppose the interior of M has a complete hyperbolic metric of nite volume. Then all but nitely many Dehn llings of M are hyperbolic manifolds.

For the Virtual Haken Conjecture there is the following result of Cooper and Long. A properly embedded compact surface S in M is *essential* if it is incompressible, boundary incompressible, and not boundary parallel. Suppose S is an essential surface in M. While S may have several boundary components, they are all parallel and so have the same slope, called the boundary slope of S. If and are two slopes, we denote their minimal intersection number, or *distance*, by $(\ ;\)$.

7.2 Theorem (Cooper-Long [12]) Let M be a compact orientable 3-manifold with torus boundary which is hyperbolic. Suppose S is a non-separating orientable essential surface in M with non-empty boundary. Suppose that S is not the ber in a bration over S^1 . Let be the boundary slope of S. Then there is a constant N such that for all slopes with $(\ ;\)$ N, the manifold $M(\)$ is virtually Haken.

Explicitly, N = 12g - 8 + 4b where g is the genus of S and b is the number of boundary components.

This result di ers from the Hyperbolic Dehn Surgery Theorem in that it excludes those llings lying in an in nite strip in $H_1(@M)$, instead of only excluding those in a compact set. Here, we will prove a Dehn surgery theorem about the Virtual Positive Betti Number Conjecture, assuming that M has a very simple Dehn lling which strongly has virtual positive betti number. Our theorem is a generalization of the work of Boyer and Zhang [5], which we discuss below.

The basic idea is this. Suppose M has a Dehn lling M() which has virtual betti number in a very strong way. By this we mean that there is a surjection $_1(M())$? where is a group all of whose nite index subgroups have lots of homology. In our application, will be the fundamental group of a hyperbolic 2-orbifold. Given some other Dehn lling M(), we would like to transfer virtual positive betti number from M() to M(). Look at $_1(M)=h$; i which we will call $_1(M();)$. This group is a common quotient of $_1(M())$ and $_1(M())$. Choose $_2(M)$ so that $_1(M)$ is a basis of $_1(M)$. Then $_1(M)$ if we think of $_1(M)$ is a quotient of $_1(M)$ we have:

$$_{1}(M(\cdot; \cdot)) = _{1}(M(\cdot)) = h i = _{1}(M(\cdot)) = h^{n}i$$
:

Thus $_1(M(\cdot; \cdot))$ surjects onto $=h^{-n}i$, where here we are confusing and its image in . So $_1(M)$ surjects onto $=h^{-n}i$. If has rapid homology growth, one can hope that $_n==h^{-n}i$ still has virtual positive betti number when n is large enough. This is plausible because adding a relator which is a large power often doesn't change the group too much. If there is an N so that $_n$ has virtual positive betti number for all n N, then $M(\cdot)$ has virtual positive betti number for all N.

Our main theorem applies when $M(\)$ is a Seifert bered space whose base orbifold is hyperbolic:

7.3 Theorem Let M be a compact 3-manifold with boundary a torus. Suppose M() is Seifert bered with base orbifold hyperbolic. Assume also

that the image of $_1(@M)$ under the induced map $_1(M)$! $_1($) contains no non-trivial element of nite order. Then there exists an N so that M() has virtual positive betti number whenever (;) N.

If is not a sphere with 3 cone points, then N can be taken to be 7.

In light of the above discussion, if we consider the homomorphism $_1(\mathcal{M}(\))$! $_1(\)=\$, Theorem 7.3 follows immediately from:

7.4 Theorem Let be a closed hyperbolic 2-orbifold without mirrors, and be its fundamental group. Let 2 be a element of in nite order. Then there exists an N such that for all n N the group

$$n = -h^{n}i$$

has virtual positive betti number. In fact, $_{\cap}$ has a $_{\cap}$ nite index subgroup which surjects onto a free group of rank 2.

If is not a 2-sphere with 3 cone points, then $N = \max f 1 = j1 + ()j/3g$. In this case, N is at most 7.

In applying Theorem 7.3, the technical condition that the image of $_1(@M)$ not contain an element of $_1$ nite order holds in many cases. For instance, Theorem 7.3 implies the following theorem about Dehn surgeries on the Whitehead link. Let W the exterior of the Whitehead link. Given a slope $_1$ on the $_2$ nstance boundary component of $_2$ we denote by $_3$ the manifold with one torus boundary component obtained by $_3$ lling along $_3$.

Theorem (9.1) Let W be the exterior of the Whitehead link. Then for all but nitely many slopes , the manifold M = W() has the following property: All but nitely many Dehn llings of M have virtual positive betti number.

In fact, our proof of this theorem excludes only 28 possible slopes (see Section 9). The complements of the twist knots in S^3 are exactly the W(1=n) for $n \ 2 \ \mathbb{Z}$. Theorem 9.1 applies to all of the slopes 1=n except for $n \ 2 \ f0$; 1g which correspond to the unknot and the trefoil. Thus we have:

7.5 Corollary Let K be a twist knot in S^3 which is not the unknot or the trefoil. Then all but nitely many Dehn surgeries on K have virtual positive betti number.

For the simplest hyperbolic knot, the gure-8, we can use a quantitative version of Theorem 7.4 due to Holt and Plesken [35] which applies in this special case. We will show:

7.6 Theorem Every non-trivial Dehn surgery on the gure-8 knot in S^3 has virtual positive betti number.

As we mentioned, Theorem 7.3 generalizes the work of Boyer and Zhang [5]. They restricted to the case where the base orbifold was not a 2-sphere with 3 cone points. In particular, they proved:

7.7 **Theorem** [5] Let M have boundary a torus. Suppose M() is Seifert bered with a hyperbolic base orbifold which is not a 2-sphere with 3 cone points. Assume also that M is small, that is, contains no closed essential surface. Then M() has virtual positive betti number whenever () 7.

The condition that M is small is a natural one as if M contains an closed essential surface, then there is a so that M() is actually Haken if ();) > 1 [15, 57].

Boyer and Zhang's point of view is di erent than ours, in that they do not set out a restricted version of Theorem 7.4. While the basic approach of both proofs comes from [2], Boyer and Zhang's proof of Theorem 7.7 also uses the Culler-Shalen theory of $SL_2\mathbb{C}$ -character varieties and surfaces arising from ideal points. From our point of view this is not needed, and Theorem 7.7 follows easily from Theorem 7.3 (see the end of Section 8 for a proof).

In Section 11, we discuss possible generalizations of Theorem 7.3 to other types of llings. In a very special case, we use toroidal Dehn llings to show (Theorem 12.1) that every Dehn lling of the sister of the gure-8 complement satis es the Virtual Positive Betti Number Conjecture.

8 One-relator quotients of 2-orbifold groups

This section is devoted to the proof of Theorem 7.4. The basic ideas go back to [2] which proves the analogous result for $=\mathbb{Z}=p$ $\mathbb{Z}=q$. Fine, Roehl, and Rosenberger proved Theorem 7.4 in many, but not all, cases where is not a 2-sphere with 3 cone points [22, 23]. In the case $=S^2(a_1;a_2;a_3)$, Darren Long and Alan Reid suggested the proof given below, and Matt Baker provided invaluable help with the number theoretic details.

Proof of Theorem 7.4 Let $_n$ be the 2-complex with marked cone points consisting of together with a disc D with a cone point of order n, where the boundary of D is attached to along a curve representing . Thus $_n = 1$

 $_1(n)$. Now the Euler characteristic of $_n$ is $_n(n) + 1 = n$, which is negative if n > 1 = j ()j. From now on, assume that n > 1 = j ()j. Suppose $_n$ contains a subgroup $_n^{\ell}$ of nite index such that if is a small loop about a cone point then $_n^{\ell}$. For instance, this is the case if $_n^{\ell}$ is torsion free. Let $_n^{\ell}$ be the corresponding cover of $_n$, so $_n^{\ell} = _1(_n^{\ell})$. Then $_n^{\ell}$ is a 2-complex without any cone points. Since $_n^{\ell}$ has negative Euler characteristic and there is no homology in dimensions greater than two, we must have $H_1(_n^{\ell}, \mathbb{Q}) \not\in 0$. Thus $_n$ has virtual positive betti number.

One can show more: Let d be the degree of the cover $\binom{\theta}{n}!$ n. The complex $\binom{\theta}{n}$ is a smooth hyperbolic surface S with d=n discs attached. From this description it is easy to check that $\binom{\theta}{n}$ has a presentation where

(# of generators) – (# of relations) =
$$(j (S)j + 1) - \frac{d}{n}$$

= $1 + d j ()j - \frac{1}{n}$ 2:

By a theorem of Baumslag and Pride [1], the group ${}^{\emptyset}_{\Pi}$ has a ${}^{\circ}$ nite-index subgroup which surjects onto ${\mathbb Z}$ ${\mathbb Z}$.

So it remains to produce the subgroups \int_{Ω}^{θ} . First, we discuss the case where is not a sphere with 3 cone points. A homomorphism $f\colon I \cap Q$ is said to preserve torsion if for every torsion element in the order of $f(\cdot)$ is equal to the order of \cdot . (Recall that the torsion elements of are exactly the loops around cone points.) The key is to show:

8.1 Lemma Suppose is not a 2-sphere with 3 cone points, and that 2 has in nite order. Given any n > 2, there exists a homomorphism : ! PSL₂ \mathbb{C} such that preserves torsion and () has order n.

Suppose we have —as in the lemma, which we will regard as a homomorphism from $_n$ to $PSL_2\mathbb{C}$. By Selberg's lemma, the group —() has a nite index subgroup—which is torsion free. We can then take $_n^{\ell}$ to be $_n^{-1}$ (). Because the lemma only requires that n>2 and the preceding argument required that n>1=j ()j, in this case we can take the N in the statement of Theorem 7.4 to be $\max f3:1+1=j$ ()jg. A case check, done in [5], shows that N is at most 7. As we will see, the proof of Lemma 8.1 is relatively easy and involves deforming Fuchsian representations—! Isom(\mathbb{H}^2) to nd—.

The harder case is when is a 2-sphere with 3 cone points, which we denote $S^2(a_1;a_2;a_3)$. Here the fundamental group can be presented as

$$hx_1; x_2; x_3 \ j \ x_1^{\partial_1} = x_2^{\partial_2} = x_3^{\partial_3} = x_1 x_2 x_3 = 1 \ i$$
:

Geometrically, x_i is a loop around the i^{th} cone point. We will show:

8.2 Lemma Let $= {}_{1}(S^{2}(a_{1}; a_{2}; a_{3}))$ where $1=a_{1}+1=a_{2}+1=a_{3}<1$. Given an element 2 of in nite order, there exists an N such that for all n N the group has a nite quotient where the images of $(x_{1}; x_{2}; x_{3}; n)$ have orders exactly $(a_{1}; a_{2}; a_{3}; n)$ respectively.

With this Lemma, we can take \int_{Ω}^{θ} to be the kernel of the given nite quotient. The proof of Lemma 8.2 involves using congruence quotients of and a some number theory. Unfortunately, unlike the previous case, the proof of Lemma 8.2 gives no explicit bound on N.

In any event, we've established Theorem 7.4 modulo Lemmas 8.1 and 8.2. □

The rest of this section is devoted to proving the two lemmas.

Proof of Lemma 8.1 Because is not a 2-sphere with 3 cone points, the Teichmüller space of is positive dimensional. Thus there are many representations of into $\text{Isom}(\mathbb{H}^2)$. We can embed $\text{Isom}(\mathbb{H}^2)$ into $\text{Isom}^+(\mathbb{H}^3) = PSL_2\mathbb{C}$ as the stabilizer of a geodesic plane. We will then deform these Fuchsian representations to produce .

Pick a simple closed curve which intersects essentially. There are two cases depending on whether a neighborhood of is an annulus or a Möbius band.

Suppose the neighborhood is an annulus. First, let's consider the case where separates into 2 pieces. In this case is a free product with amalgamation $A_{hi}B$. Let $_1$: ! PSL $_2\mathbb{C}$ be one of the Fuchsian representations. Conjugate $_1$ so that $_1()$ is diagonal. Then $_1()$ commutes with the matrices

$$C_t = \begin{array}{cc} t & 0 \\ 0 & t^{-1} \end{array} \quad \text{for } t \text{ in } \mathbb{C} :$$

For t in $\mathbb C$, let $_t$ be the representation of whose restriction to A is $_1$ and whose restriction to B is $C_{t-1}C_t^{-1}$. Consider the function $f\colon \mathbb C$! $\mathbb C$ which sends t to $\operatorname{tr}^2(_{t}(_t))$. It is easy to see that f is a rational function of t by expressing as a word in elements of A and B. We claim that f is nonconstant. First, suppose that neither of the two components of n is a disc with two cone points of order 2. In this case, can be taken to be a geodesic loop. If we restrict t to $\mathbb R$ then the family $f_{t}g$ corresponds to twisting around in the Fenchel-Nielsen coordinates on Teich(). As intersects essentially, the length of changes under this twisting and so f is non-constant. From

this same point of view, we see that that f has poles at 0 and f. If one of the pieces of f is a disc with two cone points of order 2, then naturally shrinks not to a closed geodesic, but to a geodesic arc joining the two cone points. There is still a Fenchel-Nielsen twist about f, and so we have the same observations about f in this case (think of f being obtained from a surface with a geodesic boundary component by pinching the boundary to a interval).

Since the rational function f has poles at f0; f, we have $f(\mathbb{C}) = \mathbb{C}$. So given f so that f so tha

Now we consider the case where the neighborhood of is a M"obius band. The di erence here is that you can't twist a hyperbolic structure of is along. To see this, think of constructing is a surface with geodesic boundary where the boundary is identified by the antipodal map to form is a surface. Instead, we will deform the length of is a surface in is a surface will need the hypothesis that is a surface you can see by looking at is a surface with is a surface deform the length of is a surface will need the hypothesis that is a surface you can see by looking at is a surface with is a surface deform a surface with geodesic deformance is a surface you can see by looking at is a surface you can see by looking at is a surface you can see by looking at is a surface you can see by looking at is a surface you can see by looking at is a surface you can see by looking at is a surface you can see by looking at is a surface you can see by looking at is a surface you can see by looking at is a surface you can see by looking at is a surface you can see by looking at is a surface you can see by looking at is a surface you can see by looking at is a surface you can see by looking at is a surface you can see by looking at is a surface you can see by looking at is a surface you can see by looking at is a surface you can see by looking at is a surface you can see by looking at is a surface you can see by looking at is a surface you can see by looking at is a surface you can see by looking at is a surface you can see by looking at is a surface you can see by looking at is a surface you can see by looking at is a surface you can see by looking at is a surface you can see by looking at is a surface you can see by looking at is a surface you can see by looking at is a surface you can see by looking at is a surface you can see by looking at is a surface you can see by looking at is a surface you can see by looking at is a surface you can see

The underlying surface of is non-orientable. We can assume that least one cone point since every non-orientable surface covers such an orbifold. to a cone point p. Let A be a closed neighborhood Pick an arc *a* joining $\int a$. The set A is a Möbius band with a cone point. Let B be the be the boundary of A. A small neighborhood of closure of nA. Let essentially, we can replace is an annulus, so if intersects and use the argument above. So from now on, we can assume that ! PSL₂C be a Fuchsian representation. Suppose we construct a representation : $_1(A)$! PSL $_2\mathbb{C}$ so that preserves torsion, () has order n, and $tr^{2}(()) = tr^{2}(())$. Then as $= {}_{1}(A) {}_{h,i} {}_{1}(B)$ and and conjugate on h i, we can glue and restricted to $_{1}(B)$ together to get the required representation of

Thus we have reduced everything to a question about certain representations of $_1(A)$. The group $_1(A)$ is generated by and . Choosing orientations correctly, a small loop about the cone point p is = 2 . If p has order r, then $_1(A)$ has the presentation

$$; ; = {}^{2}; {}^{r} = 1 :$$

Given any representation of $_1(A)$, we will x lifts of () and () to $SL_2\mathbb{C}$. Having done this, any word w in and has a canonical lift of (w) to $SL_2\mathbb{C}$. We will abuse notion and denote this lift by (w) as well. In this way, we can treat as though it was a representation into $SL_2\mathbb{C}$ so that, for instance, the trace of (w) is defined.

De ne a 1-parameter family of representations t for $t \ge \mathbb{C}$ as follows. Set

$$(\) = \begin{array}{ccc} 0 & 1 \\ -1 & t \end{array}$$
 and $(\) = \begin{array}{ccc} e & s \\ 0 & e^{-1} \end{array}$

where $e+e^{-1}={\rm tr}(\ (\))$ and $s=\frac{1}{t}(e^{-1}t^2-(e+e^{-1})-{\rm tr}(\ (\))$. This gives a representation of $_1(A)$ because s was chosen so that ${\rm tr}(_t(\))={\rm tr}(_t(\))$ and so $_t(\)$ also has order r in ${\rm PSL}_2\mathbb{C}$.

Let $\operatorname{Teich}(A)$ denote hyperbolic structures on A with geodesic boundary where the length of the boundary is xed to be that of the Fuchsian representation . This Teichmüller space is \mathbb{R} with the single Fenchel-Nielsen coordinate being the length of x . Note that any irreducible representation of x is conjugate to some x , and so each point in $\operatorname{Teich}(A)$ yields a Fuchsian representation x . As gets short in $\operatorname{Teich}(A)$, the curve gets long. Thus if we set $\mathsf{x} = \mathsf{tr}(\mathsf{x}(\mathsf{x}))$, then $\mathsf{x} = \mathsf{x}$ is a non-constant Laurent polynomial in x .

Let $v = {}_{2n} + {}_{2n}^{-1}$. To nish the proof of the lemma, all we need to do is nd a $t \ 2 \ \mathbb{C}$ so that $f(t)^2 = v^2$. As a map from the Riemann sphere to itself, f is onto and there are t_1 and t_2 in \mathbb{C} so that $f(t_1) = v$ and $f(t_2) = -v$. As n > 2, v is not 0 and so t_1 and t_2 are distinct. As f is non-constant and nite on \mathbb{C} , it has a pole at at least one of 0 and 1. Therefore, at least one of t_1 and t_2 is in \mathbb{C} and we are done.

Proof of Lemma 8.2 The group is naturally a subgroup of $PSL_2\mathbb{R}$. Set $b_i = 2a_i$. Let X_i be the matrix in $PSL_2\mathbb{R}$ corresponding to the generator x_i . As X_i has order a_i , it follows that $tr(X_i) = (b_i + b_i^{-1})$ where b_i is some primitive b_i th root of unity. Any irreducible 2-generator subgroup of $PSL_2\mathbb{C}$ is determined by its traces on the generators and their product, and so we can conjugate in $PSL_2\mathbb{C}$ so the X_i are:

$$X_1 = \begin{pmatrix} 0 & 1 \\ -1 & b_1 + b_1^{-1} \end{pmatrix}; X_2 = \begin{pmatrix} b_2 + b_1^{-1} & -b_3 \\ b_3 & 0 \end{pmatrix}; \text{ and } X_3 = (X_1 X_2)^{-1};$$

Henceforth we will identify with its image. The entries of the X_i lie in $\mathbb{Q}(b_1; b_2; b_3)$, and moreover are integral, so is contained in the subgroup $\mathrm{PSL}_2O(\mathbb{Q}(b_1; b_2; b_3))$. Let G be a matrix in $\mathrm{PSL}_2\mathbb{C}$ representing . Let a

be one of the eigenvalues of G. Note that a is an algebraic integer, in fact a unit, because it satis es the equation $a^2 - (\operatorname{tr} G)a + 1$ and $\operatorname{tr} G$ is integral. Let K be the eld $\mathbb{Q}(b_1;b_2;b_3;a)$. From now on, we will consider as a subgroup of $\operatorname{PSL}_2O(K)$. We will construct the required quotients of from congruence quotients of $\operatorname{PSL}_2O(K)$. Suppose f is a prime ideal of f is an algebraic integer, in fact f is an algebraic integer.

!
$$PSL_2O(K)$$
 ! PSL_2k :

What conditions do we need so that $(x_1;x_2;x_3;)$ have the right orders in PSL_2k ? Well, the eigenvalues of X_i are $f_{b_i}; \frac{-1}{b_i}g$, so as long as b_i has order b_i in k, the matrix X_i in PSL_2k also has order b_i . Similarly, if we set m=2n, then G in PSL_2k has order n if a has order m in k. Thus the following claim will complete the proof of the lemma:

8.3 Claim There exists an \mathbb{N} such that for all $n \in \mathbb{N}$ there is a prime ideal g such that if $g \in O(K) = g$ then the images of $g \in \mathcal{B}_1$; $g \in \mathcal{B}_2$; $g \in \mathcal{B}_3$; g

Let's prove the claim. The idea is to show that $a^m - 1$ is not a unit in O(K) for large m, and then just take f to be a prime ideal dividing f and f then f to be careful, though, that f to be a prime ideal dividing f and f then f then f that f is not a unit in f to be a prime ideal dividing f and f is not a unit in f to be a prime ideal dividing f and f is not a unit in f to be a prime ideal dividing f and f is not a unit in f to be a prime ideal dividing f and f is not a unit in f to be a prime ideal dividing f and f is not a unit in f and f is not a unit in f in f is not a unit in f in f in f is not a unit in f in f is not a unit in f i

A prime ideal is called *primitive* if it divides $a^m - 1$ and does not divide $a^r - 1$ for all r < m. Postnikova and Schinzel proved the following theorem:

8.4 Theorem [48, 46] Suppose that a is an algebraic integer which is not a root of unity. There there is an N such that for all n N the integer $a^n - 1$ has a primitive divisor.

The proof of Theorem 8.4 relies on deep theorems of Gelfond and A. Baker on the approximation by rationals of logarithms of algebraic numbers.

Because has in nite order, we know that a is not a root of unity. Thus Theorem 8.4 applies, and let N be as in the statement. By increasing N if necessary, we can ensure that the primitive divisor f given Theorem 8.4 does not divide any element of the f nite set

$$R = \int_{b_i}^{r} -1 j 1$$
 $r < b_i$:

It would be nice to have given a proof of Lemma 8.2 which gave an explicit bound on N. The number theory used gives \an e ectively computable constant" for N, but doesn't actually compute it. Perhaps there are other proofs of Lemma 8.2 more like that of Lemma 8.1. While $_1(S^2(a_1;a_2;a_3))$ has only a nite number of representations into $PSL_2\mathbb{C}$, if one looks at representations into larger groups there are deformation spaces where you could hope to play the same game. For instance, if one embeds \mathbb{H}^2 as a totally geodesic subspace in complex hyperbolic space $\mathbb{C}H^2$, then a Fuchsian representation deforms to a one real parameter family in $Isom^+(\mathbb{C}H^2) = PU(2;1)$. One could instead consider deformations in the space of real-projective structures, which gives rise to homomorphisms to $PGL_3\mathbb{R}$ [10]. In general, the structure of the space representations of $_1(S^2(a_1;a_2;a_3))$! $SL_n\mathbb{C}$ is closely related to the Deligne-Simpson problem [51].

We end this section by deducing Boyer and Zhang's original Theorem 7.7 from Theorem 7.3.

Proof of Theorem 7.7 Let M be a manifold with torus boundary which is small. Suppose that M() is Seifert bered with hyperbolic base orbifold which is not sphere with 3 cone points. We need to check that Theorem 7.3 be a curve so that f : q is a basis for $_1(@M)$. It su ces to does not have nite order in = 1 (). Suppose not. Then show the image of there are in nitely many Dehn llings M(i) of M where I(M(i)) surjects . The orbifold contains an essential simple closed curve which isn't a loop around a cone point. Therefore, has non-trivial splitting as a graph of groups and so acts non-trivially on a simplicial tree. Then each $_{1}(M(i))$ act non-trivially on a tree and so M(i) contains an essential surface. As in nitely many llings contain essential surfaces, a theorem of Hatcher [30] implies that M contains a closed essential surface. This is contradicts that M is small. So has in nite order and we are done. the image of П

9 Surgeries on the Whitehead link

Consider the Whitehead link pictured in Figure 8. Let W be its exterior. We will denote the two boundary components of W by \mathscr{Q}_0W and \mathscr{Q}_1W . For each \mathscr{Q}_iW , we x a meridian-longitude basis $f_{i,i}g$ with the orientations shown in the gure. With respect to one of these bases, we will write boundary slopes as rational numbers, where p + q corresponds to p = q. We will denote Dehn lling of both boundary components of W by $W(p_0 = q_0; p_1 = q_1)$. Dehn lling

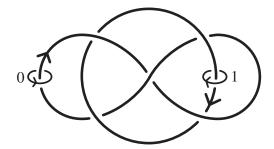

Figure 8: The Whitehead link, showing our orientation conventions for the meridians and longitudes.

on a single component of W will be denoted $W(p_0=q_0;)$ and $W(;p_1=q_1)$. As W(p=q;) is homeomorphic to W(;p=q), we will sometimes denote this manifold by W(p=q). With our conventions, W(1) is the trefoil complement, and W(-1) is the gure-8 complement. The manifold W(p=q) is hyperbolic except when p=q is in f(1):0:1:2:3:4g. The point of this section is to show:

9.1 Theorem Let W be the complement of the Whitehead link. For any slope p=q which is not in E=f1, 0, 1, 2, 3, 4, 5, 5=2, 6, 7=1, 7=2, 8, 8=3, 9=2, 10=3, 11=2, 11=3, 13=3, 13=4, 14=3, 15=4, 16=3, 16=5, 17=5, 18=5, 19=4, 24=5, 24=7g the manifold W() has the property that all but nitely many Dehn llings have virtual positive betti number.

Proof The proof goes by showing that except for p=q in E, the manifold W(p=q) has at least 2 distinct Dehn llings which are Seifert bered and to which Theorem 7.3 applies. The reason that W(p=q) has so many Seifert bered llings is because the manifolds W(1), W(2), and W(3) are all Seifert bered with base orbifold a disc with two cone points. In particular, the base orbifolds are $D^2(2/3)$, $D^2(2/4)$, and $D^2(3/3)$ respectively. Therefore, all but one Dehn surgery W(1; p=q) on W(1) is Seifert bered with base orbifold a sphere with 3 cone points. Similarly for W(2) and W(3). In fact, you can check that

W(1; p=q) Seifert bers over $S^2(2;3;jp-6qj)$ if $p=q \neq 6$.

W(2; p=q) Seifert bers over $S^2(2;4; p-4qj)$ if $p=q \neq 4$.

W(3; p=q) Seifert bers over $S^2(3;3;jp-3qj)$ if $p=q \neq 3$.

Now x a slope p=q, and consider the manifold $\mathcal{M}=\mathcal{W}(;p=q)$. We want to know when we can apply Theorem 7.3 to $\mathcal{M}(1)$, $\mathcal{M}(2)$, or $\mathcal{M}(3)$. First, we

need the base orbifold to be hyperbolic, i.e. that the reciprocals of the orders of the cone points sum to less than 1. This leads to the conditions:

For
$$\mathcal{M}(1)$$
 that $jp - 6qj > 6$.
For $\mathcal{M}(2)$ that $jp - 4qj > 4$. (2)
For $\mathcal{M}(3)$ that $jp - 3qj > 3$.

We claim that as long as the base orbifold is hyperbolic then Theorem 7.3 applies. Consider the map $_1(\mathcal{M})$! where is the fundamental group of one of the base orbifolds. Let in $@\mathcal{M}$ be the meridian coming from our meridian $_0$ of \mathcal{W} . Since intersects any of the slopes 1/2/3 once, its image in generates the image of $_1(@\mathcal{M})$. Thus we just need to check that the image of is an element of in nite order in . One can work out what the image in is explicitly (most easily by with the help of SnapPea [56]):

For
$$M(1)$$
, $V = aba^{-1}b^{-1}$ where
$$= a; b = a^2 = b^3 = (ab)^{p-6q} = 1 :$$
For $M(2)$, $V = ab^2$ where
$$= a; b = a^2 = b^4 = (ab)^{p-4q} = 1 :$$
For $M(3)$, $V = ab^{-1}$ where
$$= a; b = a^3 = b^3 = (ab)^{p-3q} = 1 :$$

It remains to check that the images of above always have in nite order in . This is intuitively clear for looking at loops which represent these elements. The suspicious reader can check that this is really the case by using, say, the solution to the word problem for Coxeter groups [6, x II.3].

Thus, Theorem 7.3 applies whenever one of the conditions in (2) holds. If p=q is such that two of (2) hold, then all but nitely many Dehn surgeries on M have virtual positive betti number. The set in $H_1(@M;\mathbb{R}) = \mathbb{R}^2$ where any one of the conditions fails is an in nite strip. So the set where a xed pair of them fail is compact, namely a parallelogram. Hence, outside a union of 3 parallelograms, at least two of the conditions hold. These 3 parallelograms are all contained in the square where jpj;jqj 100. To complete the proof of the theorem, one checks all the slopes in that square to nd those where fewer that two of (2) hold.

For most of the slopes in E, one of (2) holds, and so one still has a partial result. The slopes where none of the conditions in (2) hold are

One interesting manifold among these exceptions is the sister of the gure-8 complement W(5). We will consider that manifold in detail in Section 12.

10 The gure-8 knot

Here we prove:

10.1 Theorem Every non-trivial Dehn surgery on the gure-8 knot has virtual positive betti number.

Proof Let M be the gure-8 complement. As the gure-8 knot is isotopic to its mirror image, the Dehn lling M(p=q) is homeomorphic to M(-p=q). Now, if W is the Whitehead complement as in the last section, M = W(-1). Hence M has at least 6 interesting Seifert bered surgeries namely M(-1), M(-2) and M(-3). In (3), we saw exactly which orbifold quotients $-h^{-n}i$ arise when we try our method of transferring virtual positive betti number. By a minor miracle, Holt and Plesken have looked at exactly these quotients and shown:

10.2 Theorem [35] *Let*

$$\begin{array}{lll}
1 & a & b & a^2 = b^3 = (ab)^7 = (aba^{-1}b^{-1})^n = 1 \\
2 & a & b & a^2 = b^4 = (ab)^5 = (ab^2)^n \\
3 & a & b & a^3 = b^3 = (ab)^4 = (ab^{-1})^n = 1 \\
\end{array}$$

These groups have virtual positive betti number if n 11 for $\frac{1}{n}$ and n 6 for $\frac{2}{n}$ and $\frac{3}{n}$.

Thus M() has virtual positive betti number if any of the following hold:

It's easy to check that the only slopes for which none of these hold are f1;0;1;2g. Since $H_1(M(0)) = \mathbb{Z}$ and the Seifert bered manifolds M(1) and M(2) have virtual positive betti number, we've proved the theorem. \square

11 Other groups of the form $=h^{-n}i$ and further questions

As we have seen, groups of the form $=h^n i$, where is a Fuchsian group, are very useful for studying the Virtual Haken Conjecture via Dehn lling. So it is natural to ask: what other types of give similar results? In this section, we consider which are free products with amalgamation of nite groups. The

key source here is Lubotzky's paper [40], which gives a number of applications of these groups to the Virtual Positive Betti Number Conjecture.

For convenience, we will only discuss free products with amalgamation, but there are analogous statements for HNN extensions. Let $= A \ _C B$ be an amalgam of nite groups where C is a proper subgroup of A and B. The group acts on a tree T with nite point stabilizers. By $[50, x \ II.2.6]$, has a nite index subgroup which acts freely on T. The subgroup has to be free, and so is virtually free. It is not hard to show that if one of [A:C] and [B:C] is 3 then is virtually a free group of rank 2 [40, Lemma 2.2]. From now on, we will assume [A:C] 3. Because is virtually free, it is natural to hope that the answer to the following question is yes:

11.1 Question Let be an amalgam of nite groups, and x = 2 of in nite order. Does there exist an N such that for all n = N, the group n = -n = -n = 1 has virtual positive betti number?

Note that by Gromov, there is an N such that n is a non-elementary word hyperbolic group for all n N.

Now consider these groups in the context of Dehn lling. Suppose M is a manifold with torus boundary, and suppose is a slope where $_1(M(\))$ surjects onto , an amalgam of nite groups. Choose in $_1(@M)$ so that f; g form a basis. The proof of Theorem 7.7 shows that if M does not contain a closed incompressible surface, then the image of in has in nite order.

In general, we will say that $_1(S)$ is *weakly separable* when there is such an amalgam preserving map from $_1(N)$ to an amalgam of nite groups. A priori, this is weaker than $_1(S)$ being closed in $_1(N)$, which is in turn weaker than $_1(N)$ being subgroup separable (aka LERF).

Note that if $_1(S)$ is weakly separable, then N has virtual positive betti number as $_1(N)$ virtually maps onto a free group. If N is hyperbolic, it seems quite

possible that the fundamental group of an embedded surface is always weakly separable. If this is the case, there is no dierence between being virtually Haken and having virtual positive betti number. Subgroup separability properties for 3-manifold groups have been dicult to prove even in special cases. Weak separability also seems quite dicult to show even though the surface S is embedded.

Let M be a manifold with torus boundary which is hyperbolic. Assume that M does not contain a closed incompressible surface. Then there are always at least two Dehn llings of M which contain an incompressible surface [14, 15]. If embedded surface subgroups are weakly separable, we would expect that for most M, there are at least two slopes where $_1(M(\))$ surjects onto an amalgam of nite groups. One has to say \most" here because $M(\)$ might be a (semi-) ber or the Poincare conjecture might fail. This makes it plausible that, regardless of the truth of the virtual Haken conjecture in general, for a xed M all but nitely many Dehn llings of M have virtual positive betti number. In this context, it is worth mentioning the result of Cooper-Long [13] which says that for any such hyperbolic M all but nitely many of the Dehn llings contain a surface group. If fundamental groups of hyperbolic manifolds are subgroup separable, then this result would also imply that all but nitely many llings of M have virtual positive betti number.

One case where weak separability is known is when N = M() is irreducible and the incompressible surface S in N is a torus. Then N is Haken and, by geometrization, $_1(N)$ is residually nite. Using this it's not too hard to show that $_1(S)$ is a separable subgroup. So in this case $_1(N)$ maps to a amalgam of nite groups. In the next section, we will use these ideas in this special case to show that all of the Dehn lings on the sister of the gure-8 complement satisfy the Virtual Haken Conjecture.

12 The sister of the gure-8 complement

Let M be the sister of the gure-8 complement. The manifold M is the punctured torus bundle where the monodromy has trace -3, and is also the surgery on the Whitehead link W(5). We will use the basis (;) of $_1(@M)$ coming from the standard basis on W. We will show:

12.1 Theorem Let M be the sister of the gure-8 complement. Then every Dehn lling of M which has in nite fundamental group has virtual positive betti number.

Proof The manifold M has a self-homeomorphism which acts on $_1(@M)$ via $(\ ;\)$ V $(\ +\ ;-\)$. Let N be the lling M(4)=M(4=3). The manifold N contains a separating incompressible torus. It turns out that this torus splits N into a Seifert bered space with base orbifold $D^2(2;3)$ and a twisted interval bundle over the Klein bottle. Rather than describe the details of this splitting, we will simply exhibit the nal homomorphism from $_1(N)$ onto an amalgam of nite groups. In fact, $_1(N)$ surjects onto $_1(N)$ onto an action of order N.

According to SnapPea, the group $_1(N)$ has presentation:

$$a; b \quad ab^2 ab^{-1} a^3 b^{-1} = ab^2 a^{-2} b^2 = 1$$

where 2 (@M) becomes ab in $_1(N)$. If we add the relators $a^3 = b^4 = 1$ to the presentation of $_1(N)$, we get a surjection from $_1(N)$ onto

$$= a; b \quad a^3 = b^4 = (ab^2)^2 = 1 :$$

As S_3 has presentation x; y $x^3 = y^2 = (xy)^2 = 1$, we see that is S_3 C_2 C_4 where the rst factor is generated by fa; b^2g and the second by b.

We will need:

12.2 Lemma Let be
$$S_3$$
 C_2 C_4 and let 2 be ab. The group $C_1 = C_2 + C_4$

has virtual positive betti number for all n-10. For n<10, the group $_n$ is nite.

Assuming the lemma, the theorem follows easily. Given a slope in $_1(@M)$, if either (;4) 10 or (;4=3) 10 then M() has virtual positive betti number. The only which satisfy neither condition are E=f0, -1, 1, 1=2, 2, 3, 3=2, 4, 4=3, 5=2, 5=3, 7=3, 7=4g. One can check that the llings along these slopes either have nite $_1$ or have virtual positive betti number (the 6 hyperbolic llings in E are all among the census manifolds which we showed have virtual positive betti number in the earlier sections).

Now we will prove the lemma.

Proof of Lemma 12.2 As in the case of a Fuchsian group the key is to show:

12.3 Claim Let n 12. Then there is a homomorphism f from to a nite group Q where f is injective on the amalgam factors S_3 and C_4 and where has order n.

To prove the rest of the theorem, one can check that $_{10}$ and $_{11}$ have homomorphisms into S_{12} and $PSL_2\mathbb{F}_{23}$ respectively whose kernels have in nite H_1 . Using coset enumeration, it is easy to check that $_n$ is nite for n < 10.

12.4 Claim Suppose that f is a special representation of into S_n . Then there exists a special representation of into S_{n+6} . Also, there exists an almost special representation of into S_{n+7} .

To see this, let f be a special representation. First, we construct the representation into S_{n+6} . Let

$$L = f1; 2; ...; nq [fp_1; p_2; p_3; p_4; p_5; p_6q:$$

We will nd a special representation into S_L . Let g: ! $S_{fn;p_1;...;p_6g}$ be the special representation given by

$$g(a) = (p_1p_2p_3)(p_4p_5p_6)$$
 and $g(b) = (np_1)(p_2p_4p_3p_5)$:

It's easy to check (using that f(a) commutes with $g(b^2)$, etc.) that h(a) = f(a)g(a) and h(b) = f(b)g(b) induces a homomorphism h: ! S_L . Moreover, h(ab) = f(a)g(a)f(b)g(b) = f(a)f(b)g(a)g(b) = f(ab)g(ab). Thus h is the product of an n-cycle and a 7-cycle which overlap only in n, and so is a n + 6 cycle. So h is special.

To construct the almost-special representation, do the same thing, where g replaced is now de ned by

$$g(a) = (p_1p_2p_3)(p_4p_5p_6)$$
 and $g(b) = (np_1)(p_2p_4p_3p_5)(p_6p_7)$:

This establishes the inductive Claim 12.4.

Geometry & Topology, Volume 7 (2003)

Using the induction, to prove Claim 12.3 it sunces to show that there are special representations for n = 6/7/15/17, and that there is an almost-special representation for n = 16. These are

This completes the proof of the claim, the lemma, and thus the theorem.
